ABSTRACT:
Dental caries is the most prevalent disease affecting mankind. It affects the calcified tissue of the teeth, characterized by demineralization of the inorganic portion and destruction of the organic substance of the tooth. It is a reversible process until cavitation occurs and thus many remineralizing agents are available to halt and reverse the demineralization process before cavitation occurs. Fluoride is the most commonly used remineralizing agent. Although its efficiency is undoubtedly proven, it is still not ideal as its linked to fluorosis and limited efficiency in altered Ca and P levels. Thus in this review we aim to evaluate the literature on efficiency of Non Fluoridated remineralizing agents.

Keywords: Remineralizing agents, Non-Fluoridated, Agents.

INTRODUCTION
Dental caries is a microbial disease of the calcified tissue of the teeth, characterized by demineralization of the inorganic portion and destruction of the organic substance of the tooth. Dental caries remains as one of the most widespread disease of mankind and is a single most common chronic childhood disease.1

The oral cavity is a battlefield of activities of demineralization and remineralization. Demineralization occurs from a complex chemistry between bacteria, diet and salivary components. A drop in the pH in the oral cavity results in demineralization and the oral environment becomes unsaturated with mineral ions relative to a tooth’s mineral content. A goal of modern dentistry is to manage non-cavitated caries lesions non-invasively through remineralization in an attempt to prevent disease progression and improve aesthetics, strength, and function.1

Remineralization is defined as the process whereby calcium and phosphate ions are supplied from a source external to the tooth to promote ion deposition into crystal voids in demineralized enamel, to produce net mineral gain.

Fluoride is a known agent since decades that helps in promoting remineralization. The efficacy of fluoride in preventing dental caries is beyond dispute. However, extensive use of fluoride mainly in the form of dentifrice has contributed to a rising incidence of dental fluorosis, particularly in preschool children, due to chronic ingestion of these products. Furthermore, the ability of fluoride to promote remineralization and inhibit caries formation in the oral environment is limited by the availability of calcium and phosphate in saliva, and ultimately in plaque fluid; thus in salivary dysfunction conditions, remineralization rate is not sufficient enough to prevent caries process.
with consequent rampant caries. Fluorides are 
highly effective on smooth-surface caries than on pit and fissure caries; In certain parts of the 
world, it has been suggested that fluoride 
exposure should be limited.3-4 So there is a need for other remineralization 
agents alternative to fluorides. These agents 
are Non-fluoride topical remineralizing agents (NFTRA). They agents are commercially 
available in the form of toothpaste, chewing 
gum and varnishes. They have also been tested 
in other vehicles such as lozenges, mouth rinse and in foods and beverages.5 Some of the currently available NFTRAs are CPP-ACP, Sodium Calcium Phosphosilicate, Polyols, Nano-hydroxyapatite, Tricalcium phosphate, Dicalcium phosphate dihydrate and Theobromine.

REMINERALIZING AGENTS
Casein Phospho Peptide -Amorphous Calcium Phosphate (CPP-ACP):
There are three types of phosphopeptide based products: CPP, CPP-ACP, which contain 18% calcium ion and 30% phosphate ion in weight, and casein phosphopeptides with amorphous calcium fluoride phosphate (CPP-ACPF).CPP are peptides that are derived from the milk protein casein that are complexed with calcium and phosphate. CPP contain a cluster of phosphoseryl residues that stabilize nanoclusters of ACP in metastable solution. The CPP binds to spontaneously forming ACP nanoclusters and prevents their growth to the critical size required for nucleation and precipitation.6 The anti-caries action of CPP derivatives has a topical effect based on the following: modulation of bioavailable calcium phosphate levels because they maintain ionic phosphate and calcium super-saturation; buffer effects on plaque; increased remineralization and reduction of the hydroxyapatite solution; and difficulty for Streptococcus mutansand Streptococcus sobrinusto adhere and grow. CPP will bind to surfaces such as plaque, bacteria, soft tissue and dentin (owing to its sticky nature), providing a reservoir of bioavailable calcium and phosphate in the saliva and on the surface of the tooth. The ACP is released from the CPP complex during oral acidic challenges. Under these conditions, the CPP bound ACP would buffer plaque pH, and it would dissociate to calcium and phosphate ions. This would counteract a drop in pH thus preventing enamel demineralization. The increased calcium phosphate in the plaque buffers free calcium and phosphate ion activities and maintains a state of super-saturation of the ions in close approximation with the tooth.5 CPP-ACP is commercially available as MI paste and GC Tooth Mousse. MI paste is the first product for professional use that contains RECALDENT™ (CPP-ACP).

Sodium Calcium Phosphosilicate:
Bioactive glass is made of synthetic mineral containing sodium, calcium, phosphorous and silica (sodium calcium phospho silicate) which are all elements naturally found in the body. NovaMin is a bioactive glass in the class of highly biocompatible materials that were originally developed as bone-regenerative.7 These materials are reactive when exposed to body fluids and deposit hydroxycarbonate apatite (HCA), a mineral that is chemically similar to natural tooth mineral.8 When these particles comes in contact with saliva or water, they release sodium, calcium and phosphorous ions into the saliva which are available for remineralization of the tooth surface. These particles also attach to the tooth surface and continue to release ions and remineralize the tooth surface after the initial application. These particles have been shown, in in-vitro studies, to release ions and transform into HCA for up to two weeks. Ultimately these particles will completely transformed into HCA which is the mineral our teeth and bones are made of and results in 80% tubular occludance and desensitization.8

Polyols:
Xylitol, sorbitol, saccharin and aspartame have all been used as sugar substitutes for the
purpose of reducing dental caries in a wide variety of products including sweets, candies, chewing gum, oral hygiene products and pharmaceutical products.9

Xylitol is one of the non-sugar sweeteners permitted for use in foods. White spot lesions were observed to remineralize during clinical studies of xylitol. Xylitol is regarded as the best of all nutritive sugar substitutes with respect to caries prevention. Levine et al. in a briefing paper on xylitol, described xylitol as exhibiting both passive and active anti-caries properties.10

Remineralization is due the increased flow of saliva, rich in calcium and phosphate. Anti-caries action of xylitol is likely to be due to its effect on plaque and plaque organisms. But the biggest disadvantage of polyols is their liability to cause osmotic diarrhoea if eaten in large amounts. 11

**Nano Hydroxyapatite:**

Hydroxyapatite (HA) is one of the most biocompatible and bioactive materials and is widely used to coat artificial joints and tooth roots. Nano-sized particles are similar to the apatite crystal of tooth enamel in morphology, crystal structure and crystallinity. Recent studies have reported that addition of Nano-hydroxyapatite to toothpastes and mouthwashes potentially remineralize the artificial carious lesions.12

**Tri Calcium Phosphate:**

Tri Calcium Phosphate (TCP) or functionalized Tri Calcium Phosphate (f-TCP), is a unique technology involving mechano-chemical ball milling of tri-calcium phosphate with simple organic ingredients that results in a functionalized or bioactive tri-calcium phosphate. Tri calcium phosphate was selected over other calcium phosphate systems because it appears as a transitional phase in hydroxyapatite conversion; is biocompatible and bioactive in the oral cavity; and contains sites within its structure that can be activated with simple organic molecules. TCP is available as alpha tri calcium phosphate and functionalized beta tri calcium phosphate. Beta TCP is less soluble than alpha TCP, and thus in an unmodified form is less likely to provide bio-available calcium. It is used in products such Cerasorb®, Bio-Resorb® and Biovision®.13

Unlike other calcium-based additives, only low levels of functionalized TCP are needed to produce strong, acid-resistant mineral nucleation without negatively affecting fluoride’s proven benefits. Additionally, tricalcium phosphate can be custom-tailored for a variety of oral care products.36 TCP can be combined with a ceramic such as titanium dioxide, or other metal oxides, to limit the interaction between calcium and phosphate, and make the material more stable in solution or suspension.13

The major advantage of this calcium phosphate system is that it is stable in aqueous environment and does not affect the fluoride activity when added in the dentifrices. It has been suggested that fluoride combination with f-TCP provides greater remineralization, fluoride uptake and also decreases the dose of fluoride required to achieve the same degree of remineralization.14

**Dicalcium Phosphate Dihydrate (DCPD):**

Dicalcium phosphate dihydrate (DCPD/CaHPO4.2H2O) is an acidic calcium phosphate phase which can form from tooth mineral. The reaction of DCPD with fluoride to form fluorapatite (FAP) occurs very rapidly under appropriate conditions and this can be a mechanism for the incorporation of permanently bound fluoride.15 Under acidic conditions, the presence of calcium fluoride facilitates the conversion of DCPD to FAP which has better crystallinity. 16

**Theobromine:**

Theobromine (3,7dimethy-lxanthine), a white crystalline powder, is an alkaloid readily available in cocoa and chocolate. Its levels are higher in dark chocolates than in milk chocolates. Higher-quality chocolate tends to contain more Theobromine than lower-quality
Srilatha et al: Non Fluoridated Remineralizing Agents

chocolate. The mean Theobromine content of cocoa beans is appropriately 20.3 mg/g.¹⁷

Theobromine is a better alternative than fluoride. Theobromine can be used as an ingredient of dentifrices and even if swallowed accidentally, there are no adverse effects.

CONCLUSION
Non-fluoridated remineralizing agents alone when used also has clinical efficacy but usage of these agents along with fluoridated agents have superior efficacy. So these agents are to be used only as adjuncts to fluoridated agents so that clinical efficacy is superior and efficient.
